Abstract. A general framework for age-structured predator-prey systems is introduced. Individuals are distinguished into two classes, juveniles and adults, and several possible interactions are considered. The initial system of partial differential equations is reduced to a system of (neutral) delay differential equations with one or two delays. Thanks to this approach, physically correct models for predator-prey with delay are provided. Previous models are considered and analysed in view of the above results. A Rosenzweig-MacArthur model with delay is presented as an example.

Keywords and phrases: predator-prey, age structure, population dynamics, delay differential equations, neutral equations, Rosenzweig-MacArthur model

Mathematics Subject Classification: 92D25, 34K17, 34K40, 34K20

1. Introduction

One of the classical topics of population dynamics is the description of predator-prey interactions. Historically, the first mathematical approach for predator-prey dynamics was given by Lotka [21] and Volterra [33]. Since then more realistic models have been proposed. For example, May [22] suggested that the prey population, $R(t)$, grows logistically with rate $b_r > 0$, rather than exponentially,

$$\begin{aligned}R'(t) &= b_r R(t) \left(1 - \frac{R(t)}{K}\right) - \mu_r P(t) R(t), \\P'(t) &= -\mu_p P(t) + b_p R(t) P(t).\end{aligned}\tag{1.1}$$

In absence of prey, the predator population, $P(t)$, decreases exponentially with rate $\mu_p > 0$. Prey encounter predators and are killed at rate $\mu_r > 0$, consequently the predator population increases with rate $b_p > 0$. Stability analysis of (1.1) shows that the coexistence equilibrium, which depends also on the carrying capacity K of the prey population, is always a stable point [9]. Assuming that predators consume only a certain amount of prey, one obtains a system which is usually attributed to Rosenzweig

*Corresponding author. E-mail: marcel.mohr@bioquant.uni-heidelberg.de

and MacArthur [27], namely

$$\begin{aligned} R'(t) &= b_r R(t) \left(1 - \frac{R(t)}{K}\right) - \frac{\mu_r P(t) R(t)}{1 + R(t)}, \\ P'(t) &= -\mu_p P(t) + \frac{b_p P(t) R(t)}{1 + R(t)}. \end{aligned} \tag{1.2}$$

This system reproduces the so-called *paradox of enrichment*: If the carrying capacity K of the prey is small, the coexistence point (when it exists) is stable. For $K \rightarrow \infty$ a Hopf bifurcation occurs, the coexistence point becomes unstable and a stable periodic orbit appears [9].

In general a predator-prey system has the structure

$$\begin{aligned} R'(t) &= \alpha(R(t))R(t) - g(R(t), P(t))P(t), \\ P'(t) &= -\gamma(P(t))P(t) + h(R(t), P(t))P(t), \end{aligned} \tag{1.3}$$

where α (respectively, h) is the growth rate and g (respectively, γ) is the death rate for the prey (the predators). Several biological experiments suggest that death of prey and birth of predators depend on the total prey and/or predator population size [1]. The function g is usually called *the predation response function* and describes how probable the prey dies due to predation. In general one assumes that $g : [0, \infty) \times [0, \infty) \rightarrow [0, \infty)$ is continuous and $g(0, 0) = 0$. The simplest $g(R, P)$ is a linear function of R . For example in (1.1), we find $g(R, P) = \mu_r R$, with $\mu_r > 0$, the rate at which a prey encounters a predator. A nonlinear choice for g is also possible. For example, a Holling type II function, $g(R, P) = \frac{dR}{T+R}$, as in system (1.2), indicates that predators can only eat up a limited number of prey, whereas the function $g(R, P) = \frac{dRP}{T+RP}$ suggests that the number of encounters between predator and prey depends also on P . The function h is also called *the fecundity response function* or *numerical response function* [31] and describes how the reproduction rate of predators depends on predation. It is common to let $h : [0, \infty) \times [0, \infty) \rightarrow [0, \infty)$ be continuous, with $h(0, 0) = 0$. However, the biology suggests that there must be a certain relation between h and g , and in general $h(R, P) = cg(R, P)$, with some $c > 0$, as in systems (1.1), (1.2).

To model predator-prey interactions and include more details, one can use partial differential equations (PDEs) and consider age-structured populations [7]. Alternative modelling approaches use systems of ordinary differential equations (ODEs) or delay differential equations (DDEs) with constant delays and suggest a sort of age structure, identifying several maturity classes. The simplest models consider only two classes of individuals, namely juvenile and adult ones [2, 17, 26, 28].

In this paper we want to combine a PDE system with a DDE system and show the connections between the two modelling approaches, as it was done for single population dynamics, e.g., in [4, 24]. The paper is organised as follows. In Section 2 we consider age-structured prey and predator populations and define a threshold age, *age-at-maturity*, to distinguish juvenile from adult individuals. A newborn individual enters the juvenile class and if it survives up to the age-at-maturity it enters the adult class. In our assumptions, the age-at-maturity of prey is not necessarily the same as the one of predators. We show how to obtain a system of neutral equations with constant delays from the age structure. In this framework it is possible to find few heuristically introduced and previously published models, e.g., those in [2, 16] but also examples which are inconsistent with the biology. Results on the qualitative behaviour of solutions are provided in Section 3 Further we study a delay extension of (1.2), which is an example for the class of equations introduced in Section 2 We shall point out the sensitive dependence of the model dynamics on the delay and provide numerical examples.

Throughout this paper, the indices 1 and 2 indicate variables and parameters related to juvenile and adult individuals, respectively.

2. Model derivation

Before discussing age-structured predator-prey interactions, we briefly recall the dynamics of an isolated population structured by age. Let $n(a, t)$ be the population density with respect to the age a at time t . Biological interpretation suggests that $\lim_{a \rightarrow \infty} n(a, t) = 0$. The classical representation of an isolated population structured by age is the Lotka-Sharpe model [29],

$$\begin{aligned} \frac{\partial}{\partial t} n(a, t) + \frac{\partial}{\partial a} n(a, t) &= -\mu(a)n(a, t), \\ n(0, t) &= \int_0^\infty b(a)n(a, t) da, \\ n(a, 0) &= n_0(a). \end{aligned} \quad (2.1)$$

Here $\mu : [0, \infty) \rightarrow [0, \infty)$ and $b : [0, \infty) \rightarrow [0, \infty)$ denote the age-dependent mortality and fertility rate, respectively. These rates could also depend on the size of the population (cf. [14, 15]), however we shall not consider this case. The number of newborns at time t is $B(t) = n(0, t)$. The continuous function $n_0 : [0, \infty) \rightarrow [0, \infty)$ provides the initial age distribution. With the method of characteristics [10] one finds the explicit solution of (2.1),

$$n(a, t) = \begin{cases} n_0(a-t)e^{-\int_{a-t}^a \mu(s) ds}, & a > t, \\ B(t-a)e^{-\int_0^a \mu(s) ds}, & a \leq t. \end{cases} \quad (2.2)$$

The Lotka-Sharpe model (2.1) is our point of departure. We follow [4] and introduce a threshold age, $\tau > 0$, to distinguish juvenile individuals ($a < \tau$) from adult ones ($a > \tau$),

$$n(a, t) = \begin{cases} n_1(a, t), & a \in [0, \tau), \\ n_2(a, t), & a \in (\tau, \infty). \end{cases}$$

The total juvenile and adult populations at time $t \geq 0$ are thus, respectively,

$$n_1(t) = \int_0^\tau n_1(a, t) da \quad \text{and} \quad n_2(t) = \int_\tau^\infty n_2(a, t) da.$$

In the next section we extend this idea to model predator-prey interactions. Table 1 provides an overview of parameters and variables used.

2.1. Age-structured predator population

We consider a predator-prey model where only the predator population is structured by age. Let $p(a, t)$ denote the predator population density of individuals of age a at time t and, as done above, distinguish juvenile predators, $p_1(a, t) = p(a, t)$, $a \in [0, \tau_p)$, from adult ones, $p_2(a, t) = p(a, t)$, $a \in (\tau_p, \infty)$. Transition from the juvenile class to the adult one occurs at age $\tau_p > 0$, the age-at-maturity of the predators. The total number of predators, $P(t)$, is given by

$$P(t) = \int_0^\infty p(a, t) da = \int_0^{\tau_p^-} p_1(a, t) da + \int_{\tau_p^+}^\infty p_2(a, t) da =: P_1(t) + P_2(t).$$

Let $R(t)$ denote the number of prey at time t . When we want to model a general (non-structured) prey population interacting with juvenile and adult predators, we expect to work with a system of three equations,

$$\begin{array}{ll} \text{Prey} & R' = \alpha(R)R - g(R, P_1, P_2)\xi(P_1, P_2), \\ \text{Juvenile predators} & P_1' = \pi_1(R, P_1, P_2) - m_1(R, P_1, P_2) - \gamma_1(P_1, P_2)P_1, \\ \text{Adult predators} & P_2' = \pi_2(R, P_1, P_2) - \gamma_2(P_1, P_2)P_2. \end{array} \quad (2.3)$$

Death of prey is due to encounters $(\xi(P_1, P_2))$ with juvenile and/or adult predators. The terms $\pi_1(\pi_2)$ and m_1 describe, respectively, the recruitment into the juvenile (adult) class and the maturation from the juvenile class into the adult one. Indeed, in general these processes can be regulated by both predator classes. For the dynamics of an isolated population, a similar system has been introduced in [24]. Recruitment into the juvenile class is mostly given by a birth function, whereas into the adult class it occurs by maturation only. In [24] it was shown that $m_1(R, P_1, P_2) = \pi_2(R, P_1, P_2)$ is actually a function of $P_2(t - \tau_p)$. As in (1.3), we include the function h into (2.3) and obtain

$$\begin{aligned} R' &= \alpha(R)R - g(R, P_1, P_2)\xi(P_1, P_2), \\ P_1' &= \underbrace{h(R, P_1, P_2)\beta_1(P_1, P_2)}_{\pi_1} - m_1(R, P_1, P_2) - \gamma_1(P_1, P_2)P_1, \\ P_2' &= \pi_2(R, P_1, P_2) - \gamma_2(P_1, P_2)P_2. \end{aligned} \tag{2.4}$$

It is not straightforward to formulate correctly the above model. In particular, it might be not clear how to write the terms m_1 and π_2 . The approach we show below provides a physically correct formulation of the mathematical model. For compactness of notation, in the following we denote $g(R(t), P_1(t), P_2(t))$ and $h(R(t), P_1(t), P_2(t))$ by $g(t)$ and $h(t)$, respectively.

For the age-structured predator population, we choose birth and death rates in the form

$$\begin{aligned} b_p(a) &= b_{p,1} + (b_{p,2} - b_{p,1})H_{\tau_p}(a) + b_{p,3}\delta_{\tau_p}(a), \\ \mu_p(a) &= \mu_{p,1} + (\mu_{p,2} - \mu_{p,1})H_{\tau_p}(a), \end{aligned}$$

where $H_{\tau_p}(a)$ is the Heaviside function with a jump at $a = \tau_p$. The coefficients $b_{p,k}, \mu_{p,k}, k = \{1, 2\}$, represent birth and death rates of juveniles ($k = 1$) and adults ($k = 2$). When individuals reach sexual maturity, at age $a = \tau_p$, there may be a peak of weight $b_{p,3} \geq 0$ in the fertility rate ($\delta_{\tau_p}(a)$ is the delta distribution). A similar assumption was used in [4]. Figure 1 shows the rates $b_p(a)$ and $\mu_p(a)$.

FIGURE 1. Birth and death rates of predators are functions of the age a . Solid lines reflect the model assumptions, dashed curves represent biologically realistic smooth functions.

Taking into account effects of predation, we put up a modified Lotka-Sharpe model for $p_1(a, t)$:

$$\begin{aligned} \frac{\partial}{\partial t} p_1(a, t) + \frac{\partial}{\partial a} p_1(a, t) &= -\mu_p(a) p_1(a, t), \\ p_1(0, t) &= \int_0^\infty b_p(a) p(a, t) da \\ &= (b_{p,1} P_1(t) + b_{p,2} P_2(t) + b_{p,3} p_1(\tau_p^-, t)) h(t), \\ p_1(a, 0) &= p_1^0(a), \end{aligned} \quad (2.5)$$

with $p_1^0(a) \geq 0$ for all $a \in [0, \tau_p)$. Assuming that no individual dies at the very moment when it becomes adult, $p_2(\tau_p^+, t) = p_1(\tau_p^-, t)$, and that $\lim_{a \rightarrow \infty} p_2(a, t) = 0$, we have a similar system for $p_2(a, t)$ with initial age distribution $p_2^0(a) \geq 0$ for all $a > \tau_p$.

The total number of juvenile individuals satisfies

$$\begin{aligned} P_1'(t) &= \int_0^{\tau_p^-} \frac{\partial p_1}{\partial t}(a, t) da = - \int_0^{\tau_p^-} \left[\frac{\partial p_1}{\partial a}(a, t) + \mu_{p,1} p_1(a, t) \right] da \\ &= p_1(0, t) - p_1(\tau_p^-, t) - \mu_{p,1} P_1(t), \end{aligned}$$

and for the adult population we have

$$P_2'(t) = \int_{\tau_p^+}^\infty \frac{\partial p_2}{\partial t}(a, t) da = p_1(\tau_p^-, t) - \mu_{p,2} P_2(t). \quad (2.6)$$

With the explicit solution (2.2) of a Lotka-Sharpe model, we find for $t < \tau_p$

$$p_1(\tau_p^-, t) = p_1^0(\tau_p - t) e^{-\mu_{p,1} t},$$

and for $t \geq \tau_p$,

$$p_1(\tau_p^-, t) = \left[b_{p,1} h(t - \tau_p) P_1(t - \tau_p) + b_{p,2} h(t - \tau_p) P_2(t - \tau_p) + b_{p,3} h(t - \tau_p) p_1(\tau_p^-, t - \tau_p) \right] e^{-\mu_{p,1} \tau_p}.$$

With (2.6), for $t \geq \tau_p$ we have

$$\begin{aligned} p_1(\tau_p^-, t) &= \left[b_{p,1} h(t - \tau_p) P_1(t - \tau_p) + b_{p,2} h(t - \tau_p) P_2(t - \tau_p) \right. \\ &\quad \left. + b_{p,3} h(t - \tau_p) \left(P_2'(t - \tau_p) + \mu_{p,2} P_2(t - \tau_p) \right) \right] e^{-\mu_{p,1} \tau_p}. \end{aligned}$$

For the prey population, we have in general the first equation in (2.4). One possible choice for $\alpha(R)$ could be the logistic growth with carrying capacity $K > 0$ and net growth rate $r > 0$,

$$R'(t) = \underbrace{r \left(1 - \frac{R(t)}{K} \right)}_{\alpha(R(t))} R(t) - g(t) \xi(P_1(t), P_2(t)). \quad (2.7)$$

For $t < \tau_p$ the predator population satisfies

$$\begin{aligned} P_1'(t) &= (b_{p,1} h(t) - \mu_{p,1}) P_1(t) + b_{p,2} h(t) P_2(t) + (b_{p,3} h(t) - 1) p_1^0(\tau_p - t) e^{-\mu_{p,1} t}, \\ P_2'(t) &= -\mu_{p,2} P_2(t) + p_1^0(\tau_p - t) e^{-\mu_{p,1} t}. \end{aligned} \quad (2.8)$$

For $t \geq \tau_p$ we have

$$\begin{aligned}
P_1'(t) &= (b_{p,1}h(t) - \mu_{p,1})P_1(t) + b_{p,2}h(t)P_2(t) + (b_{p,3}h(t) - 1)b_{p,1}h(t - \tau_p)P_1(t - \tau_p)e^{-\mu_{p,1}\tau_p} \\
&\quad + (b_{p,3}h(t) - 1)(b_{p,2}h(t - \tau_p) + b_{p,3}h(t - \tau_p)\mu_{p,2})e^{-\mu_{p,1}\tau_p}P_2(t - \tau_p) \\
&\quad + (b_{p,3}h(t) - 1)b_{p,3}h(t - \tau_p)e^{-\mu_{p,1}\tau_p}P_2'(t - \tau_p), \\
P_2'(t) &= \left[b_{p,1}h(t - \tau_p)P_1(t - \tau_p) + (b_{p,2}h(t - \tau_p) + b_{p,3}h(t - \tau_p)\mu_{p,2})P_2(t - \tau_p) \right. \\
&\quad \left. + b_{p,3}h(t - \tau_p)P_2'(t - \tau_p) \right] e^{-\mu_{p,1}\tau_p} - \mu_{p,2}P_2(t).
\end{aligned} \tag{2.9}$$

We have obtained a class of systems (2.7), (2.8), respectively (2.7), (2.9), in which we can cast several examples from the literature.

Consider the system for $t \geq \tau_p$. For $b_{p,3} = 0$, we have a system of the form (2.4). It is now clear how m_1 and π_2 should be formulated in terms of $h(t - \tau_p)$ and $P_j(t - \tau_p)$, $j = 1, 2$. Assuming that juvenile individuals are not fertile ($b_{p,1} = 0$), we obtain

$$\begin{aligned}
R'(t) &= r \left(1 - \frac{R(t)}{K} \right) R(t) - g(t)\xi(P_1(t), P_2(t)), \\
P_1'(t) &= -\mu_{p,1}P_1(t) + b_{p,2}h(t)P_2(t) - b_{p,2}h(t - \tau_p)e^{-\mu_{p,1}\tau_p}P_2(t - \tau_p), \\
P_2'(t) &= b_{p,2}h(t - \tau_p)P_2(t - \tau_p)e^{-\mu_{p,1}\tau_p} - \mu_{p,2}P_2(t).
\end{aligned} \tag{2.10}$$

A proper choice of birth and death rates and of the functions h and g yields, e.g., the model by Gourley and Kuang [13]. Another system of the form (2.7), (2.8) is the third model in [26], though there is here no equation for P_1 (predators are meant to be adult predators). A ‘‘complementary’’ model to (2.7), (2.8) is provided in [16], where maturation is considered only for the prey population. In addition our approach shows that sometimes examples from the literature are inconsistent with the biological phenomena. For example Ross [28] suggests a model in which the recruitment into the adult predator population is given by $b_{p,2}R(t)P_2(t - \tau_p)$. Apparently, the delay in the prey density has been neglected.

2.2. Age-structured predator and prey population

Now we assume that the prey population is structured by age, too. As in Section 2.1, we simplify the age structure by introducing an age-at-maturity, $\tau_r > 0$, for the prey. Again, we shall consider only juvenile and adult individuals. The advantage of an age structure for the prey population is not only that we have age-dependent fertility and mortality rate, but we can also assume that predation depends on the age of the prey. This allows us to include age-specific predation into the model and to reflect different possible settings from biology. In general, a mathematical model which includes juvenile and adult predators (respectively, prey) is an extension of system (2.4) and can be described by a system of four equations

$$\begin{aligned}
R_1' &= \alpha_1(R_1, R_2)a_1(R_1, R_2) - q_1(R_1, R_2, P_1, P_2) - g_1(R_1, R_2, P_1, P_2)\xi_1(P_1, P_2), \\
R_2' &= \rho_2(R_1, R_2, P_1, P_2) - g_2(R_1, R_2, P_1, P_2)\xi_2(P_1, P_2), \\
P_1' &= h(R_1, R_2, P_1, P_2)\beta_1(P_1, P_2) - m_1(R_1, R_2, P_1, P_2) - \gamma_1(P_1, P_2)P_1, \\
P_2' &= \pi_2(R_1, R_2, P_1, P_2) - \gamma_2(P_1, P_2)P_2.
\end{aligned}$$

Here the term q_1 indicates maturation of juvenile prey and ρ_2 the recruitment into the adult prey class. As in (2.4) predation and recruitment rates can be due to all classes of individuals. For simplicity we denote the functions $g_j(\cdot)$ and $h(\cdot)$ by $g_j(t)$, $j = 1, 2$, and $h(t)$, respectively.

As in Section 2.1 we start with age-structured prey and predator populations and derive DDEs for juvenile and adult individuals. For the predator population we have essentially the systems (2.8) and (2.9). Equations for the prey population can be obtained in a similar way, however, we have to

take into account age-specific predation. We assume that only adult preys undergo predation, that is $g_1(t) \equiv 0$. This assumption fits several insect species, where individuals in the egg and larval stage are well protected [35]. It follows that $q_1(R_1, R_2, P_1, P_2) = q_1(R_1, R_2)$ and $\rho_2(R_1, R_2, P_1, P_2) = \rho_2(R_1, R_2)$.

For simplicity of computation, let $g_2(t) = \mu_{r,2}R_2(t)$ (however a different choice of g_2 is also possible, cf. Section 1). Under the assumption that juveniles die at constant rate $\mu_{r,1}$, we have

$$\mu_r(a) = \mu_{r,1} + (\xi_2(P_1(t), P_2(t))\mu_{r,2} - \mu_{r,1})H_\tau(a).$$

Let $r_1(a, t)$, $a \in [0, \tau_r)$ be the density of juvenile prey at time $t \geq 0$. Analogously, $r_2(a, t)$, $a \in (\tau_r, \infty)$ denotes the density of adult prey at time $t \geq 0$. Let $R_1(t)$ (respectively, $R_2(t)$) be the total juvenile (respectively, adult) population size at time t .

As in the previous section, we consider the PDE model for $r_1(a, t)$ and $r_2(a, t)$ and obtain a system of differential equations for R_1 and R_2 . Computation yields for $t < \tau_r$

$$\begin{aligned} R_1'(t) &= (b_{r,1} - \mu_{r,1})R_1(t) + b_{r,2}R_2(t) + (b_{r,3} - 1)r_1^0(\tau_r - t)e^{-\mu_{r,1}t}, \\ R_2'(t) &= -\mu_{r,2}\xi_2(P_1(t), P_2(t))R_2(t) + r_1^0(\tau_r - t)e^{-\mu_{r,1}t}, \end{aligned} \quad (2.11)$$

and for $t \geq \tau_r$

$$\begin{aligned} R_1'(t) &= (b_{r,1} - \mu_{r,1})R_1(t) + b_{r,2}R_2(t) + (b_{r,3} - 1)b_1R_1(t - \tau_r)e^{-\mu_{r,1}\tau_r} \\ &\quad + (b_{r,3} - 1)(b_{r,2} + b_{r,3}\mu_{r,2})e^{-\mu_{r,1}\tau_r}R_2(t - \tau_r) \\ &\quad + (b_{r,3} - 1)b_{r,3}e^{-\mu_{r,1}\tau_r}R_2'(t - \tau_r), \\ R_2'(t) &= [b_{r,1}R_1(t - \tau_r) + (b_{r,2} + b_{r,3}\mu_{r,2})R_2(t - \tau_r) \\ &\quad + b_{r,3}R_2'(t - \tau_r)]e^{-\mu_{r,1}\tau_r} - \mu_{r,2}\xi_2(P_1(t), P_2(t))R_2(t). \end{aligned} \quad (2.12)$$

Hence we have obtained a general class of predator-prey systems in which we can cast several examples from the literature (of course a proper choice of birth and death rates and of the functions h and ξ_2 is necessary). As for the systems (1.3) and (2.4), also in this case there is a certain relation between predation response and fecundity response of predators. It is meaningful to choose $h(t)$ proportional to a linear combination of $g_1(t)$ and $g_2(t)$, that is, the growth rate of predators depends on the (eaten) prey (cf. [3, 20, 26]). If predation is only due to adult predators, then we have $\xi_j(P_1, P_2) = \xi_j(P_2)$, $j = 1, 2$.

It is worthy of note that often in previous models no distinction between juvenile and adult individuals has been made (cf. [2, 20, 26]). Indeed, to the best of our knowledge, there is no example in literature which proposes a mathematical model for four populations P_1, P_2, R_1, R_2 . A comparison with our model suggests that, mostly, heuristically introduced equations describe the dynamics of adult prey and predators. A special case, in which predators and prey species have the same maturation time was given in [26]. Further, when populations of juveniles and adult individuals are explicitly introduced, e.g., in [13], then usually it is assumed that juvenile individuals are not fertile, that is, $b_1 = 0$ as in (2.10).

Our approach guarantees that the obtained mathematical model is consistent with biology. This is not the case for all models. For example in [3] death of prey is described by the term $-\mu_r P(t)R(t - \sigma)$, whereas recruitment into predator population is given by $bP(t - \tau)R(t)$. The two delays σ and τ seem to have no connection with maturation times and it remains unclear how they should be motivated from a biological point of view.

In general, prey and predators are not characterised by the same age-at-maturity, that is, we could have $\tau_p \neq \tau_r$. Hence, there are three time intervals which we have to consider separately. Let $\tau_{min} := \min\{\tau_p, \tau_r\}$ and $\tau_{max} := \max\{\tau_p, \tau_r\}$. For $t \in [0, \tau_{min})$, we have a nonautonomous ODE system (2.8), (2.11), whose right-hand side depends on the initial age distribution of the underlying PDE model. For $t \in [\tau_{min}, \tau_{max})$, we have a system consisting of two nonautonomous ODEs and two neutral

<i>Symbol</i>	<i>Description</i>

$P_j(t)$	size of juvenile/adult predator population at time t
$r(a, t)$	density of prey of age a at time t
$r_j(a, t)$	density of juvenile/adult prey of age a at time t
$R(t)$	size of prey population at time t
$R_j(t)$	size of juvenile/adult prey population at time t
τ_p	age at maturity of predator
τ_r	age at maturity of prey
$\mu_{p,j}$	death rate of juvenile/adult predator
$b_{p,j}$	fertility rate of juvenile/adult predator
$b_{p,3}$	fertility rate of predator at age τ_p
$\mu_{r,j}$	death rate of juvenile/adult prey
$b_{r,j}$	fertility rate of juvenile/adult prey
$b_{r,3}$	fertility rate of prey at age τ_r

TABLE 1. Variables and parameters for the models in Section 2. The indices $j = 1$ and $j = 2$ indicate juvenile and adult individuals, respectively. All quantities are nonnegative.

equations with constant delay. If $\tau_{min} = \tau_p$, the system is given by (2.9) – (2.11), whereas it is given by (2.8), (2.12), if $\tau_{min} = \tau_r$. In both cases, we have a combination of initial data given by the initial age distribution of the PDE model and the solution of the system on $[0, \tau_{min})$. For $t \in [\tau_{max}, \infty)$, we have a system of four neutral equations with two constant delays (2.9), (2.12). Here the initial data is given by the solution on $[0, \tau_{max})$.

In the general settings presented above, we have assumed that there is a peak of weight $b_{p,3}$ in the birth rate when individuals reach maturity. Such a peak in the fertility rate was observed, e.g., in loggerhead turtles [6], as well as in many insect populations [35]. From a mathematical point of view, $b_{p,3} \neq 0$ yields a neutral equation. To the best of our knowledge, there are only few other examples of neutral equations for predator-prey interactions. Kuang [20] suggests a system with neutral term in the equation for the prey,

$$R'(t) = rR(t) \left(1 - \frac{R(t - \tau_r) + R'(t - \tau_r)}{K} \right) - P(t)\rho(R(t)). \quad (2.13)$$

This model is essentially obtained by extending the “neutral logistic equation” in [12] with a further death term due to predation. The formal derivation of a DDE from the age structure yields in (2.12) a delay in the recruitment term of the prey, in contrast to equation (2.13), where the delay appears in the death term (see also [4] for similar observations for single population dynamics).

However, in many species, one does usually not observe a peak in the fertility rate, but rather a jump, when individuals become sexually mature, see e.g. the data set in [25]. In the following we shall neglect the peak in $b(a)$, both for the prey and for the predator population, i.e., $b_{p,3} = 0 = b_{r,3}$. This assumption reduces the problem to a system of (non-neutral) equations with constant delays.

3. Analytical Results

Here we provide some analytical results for the model with one delay. Much more challenging is the case of two (or several) delays, which shall be studied in a forthcoming paper.

Consider the model (2.10) for $t \geq \tau_p$, and let $g(t) = g(R(t), P_2(t))$ and $h(t) = h(R(t), P_2(t))$. For simplicity of notation, we omit the p -index in the coefficients and in the delay. For $t < \tau$ we have

$$R'(t) = r \left(1 - \frac{R(t)}{K} \right) R(t) - g(t)\xi(P_1(t), P_2(t)), \quad (3.1)$$

$$P_1'(t) = -\mu_1 P_1(t) + b_2 h(t) P_2(t) - p_1^0(\tau - t) e^{-\mu_1 t}, \quad (3.2)$$

$$P_2'(t) = -\mu_2 P_2(t) + p_1^0(\tau - t) e^{-\mu_1 t}. \quad (3.3)$$

Taken together the model, which describes the dynamics in the whole interval $[0, \infty)$ can be seen as a general formulation of the system by Gourley and Kuang [13].

Preservation of positivity is a crucial factor in mathematical biology. However, systems of DDEs can possibly have negative solutions even when the initial functions are nonnegative [30]. In the following we provide criteria to guarantee nonnegative solutions of (2.10).

The right-hand side of (3.1)–(3.3) depends on the initial age distribution $p_1^0(a)$ of a PDE system of the form (2.1) for the juvenile predator. If $p_1^0(a) \geq 0$, $a \geq 0$ is known, we take the solution of (3.1)–(3.3) as history function for (2.10) and we obtain nonnegative solutions. Now consider the case in which $p_1^0(a)$ is not known. Following [4], we start with (3.3) and find

$$\frac{d}{dt} (P_2(t) e^{\mu_2 t}) e^{(\mu_1 - \mu_2)t} = p_1^0(\tau - t) \quad (\geq 0).$$

That is, the function $P_2(t) e^{\mu_2 t}$ is nondecreasing on $[0, \tau]$. Integration in $[0, \tau]$ yields

$$P_1(0) = P_2(\tau) e^{\mu_1 \tau} - P_2(0) - (\mu_1 - \mu_2) \int_0^\tau P_2(t) e^{\mu_1 t} dt. \quad (3.4)$$

We use (3.2) to substitute the term $p_1^0(\tau - t) e^{-\mu_1 t}$ and obtain

$$P_1'(t) = -\mu_1 P_1(t) + (b_2 h(t) - \mu_2) P_2(t) - P_2'(t).$$

The last equation can be solved with variation of constants and integration by parts,

$$\begin{aligned} P_1(t) &= (P_1(0) + P_2(0)) e^{-\mu_1 t} - P_2(t) + \int_0^t (b_2 h(s) - \mu_2) P_2(s) e^{\mu_1(s-t)} ds \\ &\quad + \mu_1 \int_0^t P_2(s) e^{\mu_1(s-t)} ds. \end{aligned} \quad (3.5)$$

As the equation (3.1) is an ODE, there is no problem with positivity of solutions, as long as we choose a nonnegative initial value $R(0)$. The solution exists and is unique, given continuously differentiable g and ξ .

We define an operator $T : (C[0, \tau])^2 \rightarrow C[0, \tau]$ so that $(T(R, P_2))(t) = P_1(t)$ for $t \in [0, \tau]$ and $P_1(t)$ is given by (3.5) with $P_1(0)$ as in (3.4). The cone \mathcal{K} is defined by

$$\mathcal{K} := \left\{ (R, P_1, P_2) \in (C[0, \tau])^3 : P_2(0) \geq 0, \right. \\ \left. P_2(t) e^{\mu_2 t} \text{ is nondecreasing in } [0, \tau], P_1 = T(R, P_2), R(0) \geq 0 \right\}.$$

Proposition 3.1. *Let a PDE system of the form (2.1) for $p_1(a, t)$ be given with initial age distribution $p_1^0(a) \geq 0$. Then the functions $R(t), P_1(t), P_2(t)$ defined in Section 2.1 satisfy system (3.1)–(3.3) and $(R, P_1, P_2)|_{[0, \tau]} \in \mathcal{K}$.*

Conversely, for $(\tilde{R}, \tilde{P}_1, \tilde{P}_2) \in \mathcal{K}$, there is an initial age distribution $p_1^0(a) \geq 0$ such that the solution (R, P_1, P_2) of the system (3.1)–(3.3) satisfies $(R, P_1, P_2)|_{[0, \tau]} = (\tilde{R}, \tilde{P}_1, \tilde{P}_2)$.

Proof. The first part has already been shown. The rest of the proof follows similar to [4], with the difference that here the operator T has two arguments.

3.1. Linearised stability

3.1.1. The case of no delay

First we consider (2.10) with $\tau = 0$. From a biological point of view, this means that newborn individuals are sexually mature. The juvenile class P_1 loses its original meaning. Evidently, $\lim_{t \rightarrow \infty} P_1(t) = 0$. Fixed points of the system are the trivial equilibrium $E_0 = (0, 0, 0)$, in which we find neither prey nor predator, the point $E_R = (K, 0, 0)$, where only prey are present and a *coexistence equilibrium* $E_C = (R^*, 0, P_2^*)$, with $R^* \in (0, K)$ and $P_2^* > 0$. Such an equilibrium is obtained as the intersection of the curve $b_2 h(R^*, P_2^*) = \mu_2$ and the prey isocline $rR^*(1 - \frac{R^*}{K}) = g(R^*, P_2^*)\xi(0, P_2^*)$ in the positive cone. The number of coexistence points depends on the choice of the functions h and g .

We denote by g_R and g_{P_2} the derivative of g with respect to R and P_2 , respectively (analogously for h). The biology suggests that the functions h and g are nondecreasing both in P_2 and R , hence all the partial derivatives are nonnegative. This assumption includes the possibility that, when the prey population has reached its carrying capacity, the prey dies for reasons different than predation, e.g., external harvesting or migration. However, we assume that $g_R(R, 0) = 0$, for all $R \geq 0$, i.e., in absence of predators no prey dies. The function $\xi(P_1, P_2)$ is nondecreasing in both components.

Proposition 3.2. *The trivial equilibrium $E_0 = (0, 0, 0)$ is always unstable. The point $E_R = (K, 0, 0)$ is locally asymptotically stable if $\mu_2 > b_2 h(K, 0)$.*

Proof. The proof follows with standard linear stability theory. Computation can be found in [23].

Consider the coexistence equilibrium $E_C = (R^*, 0, P_2^*)$. As the P_1 -direction is always stable, it is sufficient to investigate the matrix $A = (a_{i,k})_{i,k=1,2}$,

$$A = \begin{pmatrix} r - 2\frac{r}{K}R^* - g_R(R^*, P_2^*)\xi(0, P_2^*) & -(g_{P_2}(R^*, P_2^*)\xi(0, P_2^*) + g(R^*, P_2^*)\xi_{P_2}(0, P_2^*)) \\ b_2 h_R(R^*, P_2^*)P_2^* & b_2 h_{P_2}(R^*, P_2^*)P_2^* \end{pmatrix}.$$

Note that $a_{1,2} \leq 0$, whereas $a_{2,1}$ and $a_{2,2}$ are nonnegative. The coexistence point is stable when $\det(A) > 0$ and $\text{tr}(A) < 0$.

3.1.2. The case $\tau > 0$

As in the case $\tau = 0$ we have the equilibria $E_0 = (0, 0, 0)$ and $E_R = (K, 0, 0)$. Coexistence equilibria depend on the choice of h and g . In Section 3.2 we show an example in which the coexistence point $E_C = (R^*, P_1^*, P_2^*)$ is uniquely determined. We say a coexistence point is *feasible* when it is in the positive cone and all its components are bounded.

Linearised stability analysis [30] allows to reduce the problem to a standard linear equation of the form $x'(t) = Ax(t) + Bx(t - \tau)$. It is immediate to prove that the delay has no influence on the stability of the trivial equilibrium E_0 . It is locally asymptotically stable if $r < g_R(0, 0)\xi(0, 0)$ holds, otherwise unstable [23].

Linearisation about the point E_R yields the characteristic equation

$$(\lambda + r + g_R(K, 0)\xi(0, 0))(\lambda + \mu_1)(\lambda + \mu_2 - e^{-(\mu_1 + \lambda)\tau} b_2 h(K, 0)) = 0.$$

The characteristic roots are $\lambda_1 = -r - g_R(K, 0)\xi(0, 0) \in \mathbb{R}$, $\lambda_2 = -\mu_1 \in \mathbb{R}$ and λ_3 which is given by the equation

$$\lambda + \mu_2 - e^{-(\mu_1 + \lambda)\tau} b_2 h(K, 0) = 0. \quad (3.6)$$

This equation has the form $\lambda - a - be^{-\tau\lambda} = 0$, with $a = -\mu_2$ and $b = e^{-\mu_1\tau}b_2h(K, 0) > 0$ for all $\tau > 0$. The delay in the coefficients of the characteristic equation can make the stability analysis challenging. However, Theorem 6 in [11] ensures that equation (3.6) has a real dominant root (the condition $-e^{-1} \leq b\tau e^{-a\tau}$ holds for all $\tau > 0$). Hence it is sufficient to investigate the real characteristic roots of (3.6), which are given by the intersections of the line $y = x + \mu_2$ with the curve $y = b_2h(K, 0)e^{-\mu_1\tau}e^{-x\tau}$.

Proposition 3.3. *The equilibrium E_R of system (2.10) is locally asymptotically stable if*

$$r + g_R(K, 0)\xi(0, 0) > 0 \quad \text{and} \quad \mu_2 > b_2h(K, 0)e^{-\mu_1\tau}.$$

Assume that there is a uniquely determined coexistence point $E_C = (R^*, P_1^*, P_2^*)$. For simplicity of computation we assume that predation is only due to adult predators, i.e., $\xi(P_1, P_2) = \xi(P_2)$. We are interested in stability properties of E_C with respect to the delay $\tau > 0$. To this purpose we shall make use of results in [3, Sec. 2]. Linearisation of (2.10) about E_C yields the characteristic equation $G(\lambda; \tau) = 0$, with

$$\begin{aligned} G(\lambda; \tau) = & (\lambda + \mu_1) \left[(\lambda + \mu_2 - e^{-(\lambda+\mu_1)\tau} (b_2h(R^*, P_2^*) + b_2h_{P_2}(R^*, P_2^*)P_2^*)) \right. \\ & \cdot \left(\lambda - r + 2\frac{rR^*}{K} + g_R(R^*, P_2^*)\xi(P_2^*) \right) \\ & \left. + e^{-(\lambda+\mu_1)\tau} b_2h_R(R^*, P_2^*)P_2^* \left(g_{P_2}(R^*, P_2^*)\xi(P_2^*) + g(R^*, P_2^*)\xi'(P_2^*) \right) \right]. \end{aligned}$$

Hence we have one real root $\lambda = -\mu_1$, whereas other roots are determined by the term in the square brackets. The above characteristic equation can be written in the form

$$P(\lambda; \tau) + Q(\lambda; \tau)e^{-\lambda\tau} = 0,$$

with

$$\begin{aligned} P(\lambda; \tau) = & \lambda^2 + \left(2\frac{r}{K}R^* + g_R(R^*, P_2^*)\xi(P_2^*) - r + \mu_2 \right) \lambda \\ & + \left(2\frac{r}{K}R^* + g_R(R^*, P_2^*)\xi(P_2^*) - r \right) \mu_2, \\ Q(\lambda; \tau) = & -e^{-\mu_1\tau} (b_2h(R^*, P_2^*) + b_2h_{P_2}(R^*, P_2^*)P_2^*) \lambda \\ & - e^{-\mu_1\tau} \left[(b_2h_R(R^*, P_2^*) + b_2h_{P_2}(R^*, P_2^*)P_2^*) \left(2\frac{r}{K}R^* + g_R(R^*, P_2^*)\xi(P_2^*) - r \right) \right. \\ & \left. - b_2h_R(R^*, P_2^*) (g_{P_2}(R^*, P_2^*)\xi(P_2^*) + g(R^*, P_2^*)\xi'(P_2^*)) P_2^* \right]. \end{aligned}$$

Let

$$\begin{aligned} \beta &= 2\frac{r}{K}R^* + g_R(R^*, P_2^*)\xi(P_2^*) - r, \\ \gamma &= b_2h(R^*, P_2^*) + b_2h_{P_2}(R^*, P_2^*)P_2^*, \\ \varepsilon &= b_2h_R(R^*, P_2^*) \left(g_{P_2}(R^*, P_2^*)\xi(P_2^*) + g(R^*, P_2^*)\xi'(P_2^*) \right) P_2^*, \end{aligned} \tag{3.7}$$

and obtain

$$P(\lambda; \tau) = \lambda^2 + (\beta + \mu_2)\lambda + \mu_2\beta, \quad Q(\lambda; \tau) = -e^{-\mu_1\tau}\gamma\lambda - e^{-\mu_1\tau}(\gamma\beta - \varepsilon).$$

Stability properties of E_C are determined by the real part of the characteristic roots. Define the functions

$$\begin{aligned} M : [0, \infty) &\rightarrow \mathbb{R}, \quad \tau \mapsto \beta^2 + \mu_2^2 - e^{-2\mu_1\tau}\gamma^2, \\ N : [0, \infty) &\rightarrow \mathbb{R}, \quad \tau \mapsto e^{-2\mu_1\tau}(\gamma\beta - \varepsilon)^2 - \mu_2^2\beta^2. \end{aligned}$$

As the delay appears in the coefficients of the characteristic equation (note that τ is also in the coordinates of the point E_C) it is difficult to determine precisely the value of the delay at which stability switches occur. However, we have the following result.

Theorem 3.4. *Let $\beta(\gamma - \mu_2 e^{\mu_1 \tau}) \neq \varepsilon$ with $\tau \geq 0$. The stability of E_C depends on the value of the delay $\tau \geq 0$ as follows.*

- (1) *Assume $M(\tau) \geq 0$. If τ increases and enters $S_c := \{\tau \in \mathbb{R}_0 : M(\tau) \geq 0, N(\tau) > 0\}$, stability switches may occur as τ increases within S_c . If $\tau \notin S_c$, no stability switch occurs.*
- (2) *Assume $M(\tau) < 0$. If τ increases and enters $S_c := \left\{\tau \in \mathbb{R}_0 : M(\tau) < 0, N(\tau) \geq -\frac{M(\tau)^2}{4}\right\}$, stability switches may occur as τ increases within S_c . If $\tau \notin S_c$, no stability switch occurs.*

Proof. We verify the hypothesis of [3, Sec. 2]. The functions P and Q do not have any common imaginary root $\lambda = \pm iy$, $y \in \mathbb{R}_+$. Indeed

$$P(iy; \tau) = -y^2 + i(\beta + \mu_2)y + \mu_2\beta = 0 = -e^{-\mu_1 \tau} (i\gamma y + \gamma\beta - \varepsilon) = Q(iy; \tau)$$

only for $y = 0$. Further we have $\overline{P(-iy, \tau)} = P(iy, \tau)$ and $\overline{Q(-iy, \tau)} = Q(iy, \tau)$ for $y \in \mathbb{R}$ and for all $\tau \geq 0$. Observe that

$$P(0; \tau) + Q(0; \tau) = \beta(\mu_2 - \gamma e^{-\mu_1 \tau}) - \varepsilon e^{-\mu_1 \tau} \neq 0, \quad \text{for all } \tau \geq 0.$$

Some computation (see [23]) shows that for all $\tau \geq 0$,

$$\limsup\{|Q(\lambda, \tau)|/|P(\lambda, \tau)| : |\lambda| \rightarrow \infty, \Re(\lambda) \geq 0\} < 1.$$

Consider purely imaginary roots $\lambda = iy$ for $y \in \mathbb{R}_+$. Then we have

$$\begin{aligned} P_R &:= \Re(P(iy; \tau)) = \mu_2\beta - y^2, & P_I &:= \Im(P(iy; \tau)) = (\beta + \mu_2)y, \\ Q_R &:= \Re(Q(iy; \tau)) = -e^{-\mu_1 \tau}(\gamma\beta - \varepsilon), & Q_I &:= \Im(Q(iy; \tau)) = -e^{-\mu_1 \tau}\gamma y. \end{aligned}$$

Hence,

$$F(y; \tau) = P_R^2 + P_I^2 - Q_R^2 - Q_I^2 = y^4 + M(\tau)y^2 - N(\tau).$$

With $z := y^2$, the zeros of $F(y; \tau)$ are given by $y_{1,2} = \sqrt{z_{\pm}}$ and $y_{3,4} = -\sqrt{z_{\pm}}$, where

$$z_{\pm} = -\frac{M(\tau)}{2} \pm \sqrt{\frac{M(\tau)^2}{4} + N(\tau)}.$$

For each $\tau \geq 0$ we have at most four different real roots of $F(y; \tau)$, hence also the last hypothesis is satisfied. We search for values of τ such that F has at least one strictly positive root. If $M(\tau) \geq 0$, z_- is always negative or complex, but $z_+ > 0$ if and only if $N(\tau) > 0$. If $M(\tau) < 0$, $z_- > 0$ if and only if $N(\tau) > 0$ and $z_+ > 0$ if and only if $N(\tau) \geq -\frac{M(\tau)^2}{4}$.

3.2. A Rosenzweig-MacArthur DDE model

An example for the class of problems (2.10) is given by a delayed version of the Rosenzweig-MacArthur model (1.2). We choose the functions $h(t) = h(R(t)) = R(t)/(1 + R(t))$, $g(t) = g(R(t)) = bh(t)$, $b > 0$, and $\xi(P_1(t), P_2(t)) = \xi(P_2(t)) = P_2(t)$. These are all C^1 -functions and that $h(0) = 0 = g(0)$. As observed in the previous section, the P_1 -equation is not relevant for the dynamics of the whole system. Hence, we focus on the system

$$\begin{aligned} R'(t) &= R(t) \left(1 - \frac{R(t)}{K}\right) - b \frac{R(t)}{1 + R(t)} P_2(t), \\ P_2'(t) &= -\mu P_2(t) + b \frac{R(t - \tau)}{1 + R(t - \tau)} P_2(t - \tau) e^{-\mu_1 \tau}. \end{aligned} \tag{3.8}$$

Assume that we have nonnegative continuous initial data $R(\vartheta), P_2(\vartheta)$ on $-\tau \leq \vartheta \leq 0$. Then it is easy to prove that the solutions $(R(t), P_2(t))$ of (3.8) are nonnegative for all $t \geq 0$ [23].

In the case $\tau = 0$, the dynamics of (3.8) is known [27]. Beside the trivial equilibrium, which always exists, system (3.8) has a unique coexistence equilibrium $E_C = (R^*, P_2^*)$ with

$$R^* = \frac{\mu}{b - \mu}, \quad P_2^* = \frac{1}{b - \mu} \left(1 - \frac{\mu}{K(b - \mu)} \right).$$

The coexistence equilibrium is feasible only if $b > \mu$ and $K > K_0^* = \frac{\mu}{b - \mu}$. The point E_C is locally asymptotically stable if $K < \frac{b + \mu}{b - \mu}$, a Hopf bifurcation occurs at $K_1^* = \frac{b + \mu}{b - \mu}$ and the point becomes unstable.

In the case $\tau > 0$, for $b > \mu e^{\mu_1 \tau}$ and $K < \frac{\mu}{b e^{-\mu_1 \tau} - \mu}$, there is only one nontrivial equilibrium $E_R = (K, 0)$, which is stable for all $\tau \geq 0$. For $b > \mu e^{\mu_1 \tau}$ and $K > \frac{\mu}{b e^{-\mu_1 \tau} - \mu}$ beside $E_R = (K, 0)$, we find a unique coexistence point $E_C = \left(\frac{\mu}{b e^{-\mu_1 \tau} - \mu}, \frac{1}{b} \left(1 - \frac{R^*}{K} \right) (1 + R^*) \right)$, whose stability depends on τ . Note that with a delay $\tau > 0$, the population size of the prey at the coexistence point E_C is higher than in the case $\tau = 0$. This is biologically meaningful as we assumed that only adult predator hunt the prey (during the predator maturation time, the prey population size can increase).

We determine the set S_c in which stability switches can occur. With (3.7) we find the values

$$\beta = \frac{2\mu}{K(b e^{-\mu_1 \tau} - \mu)} - e^{\mu_1 \tau} \left(\frac{\mu}{b} + \frac{\mu}{Kb} \right), \quad \gamma = \mu e^{\mu_1 \tau}, \quad \varepsilon = \mu e^{\mu_1 \tau} \left[1 - e^{\mu_1 \tau} \left(\frac{\mu}{b} + \frac{\mu}{Kb} \right) \right],$$

and we have that $M(\tau) = \beta^2 \geq 0$. Hence, stability switches occur for $\tau \geq 0$ such that $N(\tau) > 0$, or equivalently for $\tau > 0$ such that

$$\varepsilon - 2\mu e^{\mu_1 \tau} \beta > 0 \quad \Leftrightarrow \quad 1 + e^{\mu_1 \tau} \left(\frac{\mu}{b} + \frac{\mu}{Kb} \right) - \frac{4\mu}{K(b e^{-\mu_1 \tau} - \mu)} > 0.$$

That is, we want to find values $x > 0$ such that

$$x^2 + \frac{3b}{\mu(1 + K)}x - \frac{Kb^2}{\mu^2(1 + K)} < 0 \quad (3.9)$$

holds. Zeros of (3.9) are

$$x_{\pm} = -\frac{3b}{2\mu(1 + K)} \pm \sqrt{\frac{9b^2}{4\mu^2(1 + K)^2} + \frac{Kb^2}{\mu^2(1 + K)}}.$$

It is easy to see that $x_- < 0$. Thus $N(\tau) > 0$ holds for all $\tau \in S_c = [0, \tau_{max})$, with $\tau_{max} = \ln(x_+)/\mu_1$. For $\tau \in [0, \tau_{max})$ we can observe stability switches, for $\tau > \tau_{max}$ the stability of the coexistence point does not change when τ changes. An example is shown in Figure 2. We observe that both K and τ can be chosen as bifurcation parameters for (3.8). For $\tau = 0$ and $K \in (0, K_0^*)$ the point E_R is stable, whereas for $K \in (K_0^*, K_1^*)$ the coexistence equilibrium E_C is locally asymptotically stable and when the carrying capacity K becomes larger than K_1^* a limit cycle appears. The inclusion into the model of a maturation delay seems to shift forward the destabilisation of the equilibria. That is, for $\tau > 0$ and $K \in (0, K_R^*(\tau))$, with $K_R^*(\tau) \leq K_R^*(0) = K_0^*$ the point E_R is stable, whereas for $K \in (K_R^*(\tau), K_C^*(\tau))$ with $K_C^*(\tau) \leq K_C^*(0) = K_1^*$ the coexistence equilibrium E_C is locally asymptotically stable. However, for $K > K_C^*(\tau)$ an increase in the delay can lead to damped oscillations and again to a stable coexistence equilibrium, cf. Figure 2. A last numerical test shows how periodic solutions depend on the delay and on the other parameters. We consider periodic solutions and compute oscillation amplitudes (over one period of the periodic solution). Figure 3 shows oscillation amplitudes for the solution P_2 in dependence of the delay and of one other parameters. Observe that there is no periodic solution for very large values of the delay. From a biological point of view, a very large age-at-maturity implies that predators stay

long in the juvenile phase and it takes a long time for them to become active predators. During this time the prey can increase and reach a certain density such that the predation effects are not very relevant. This leads to a stable coexistence of predators and prey, rather than the well-known oscillatory dynamics.

FIGURE 2. Effect of the delay on the solution of the system (3.8). Numerical simulations were performed with the MATLAB® solver `dde23`. For this simulations we choose $K = 5$, $b = 1$, $\mu = 0.6$, $\mu_1 = 0.4$ and three values of the delay τ . We may observe stability switches for $\tau \in [0, \tau_{max})$, with $\tau_{max} = 0.3728$.

4. Remarks

In this paper we proposed an approach to formally derive a general class of predator-prey models with delay from age-structured populations. The obtained framework is useful to classify examples from literature and to recognise that, in some cases, the mathematical model is not consistent with biology. We considered two possible settings. In the first case we chose a homogeneous prey population interacting with an age-structured predator population, whereas in the second one both prey and predator populations were age-structured. A rigorous mathematical analysis of the latter case is quite challenging and has been postponed to a forthcoming paper. Our work focused on the model with the age-structured predator population. We provided criteria to guarantee nonnegative solutions and investigated the stability properties of the unique coexistence equilibrium E_C with respect to the age-at-maturity of the predators, τ , which we treated as a bifurcation parameter.

Models of the form (2.3) are also known as stage-structured predator-prey models with juveniles and adult predators [34]. A structure in the population allows to characterise individuals according to age, size, physiological state or other properties. From a modelling point of view, this often leads to a PDE approach in terms of transport equations, e.g., as in (2.5). Introducing a threshold in the age, we define two “compartments” or “stages”, i.e., juveniles and adults. This threshold expresses the age at which individuals transit from one compartment to the other (the age-at-maturity). Due to the linear relation between time and age, we obtain a DDE system for juveniles and adults. Similar results would hold considering a size-structured population and introducing a threshold-size for the compartment transition [18, 19]. However, size might not evolve linearly in time and therefore the derivation of a DDE system might be challenging. The concept of a stage structure within a population is even more general than the one of a structure in age, since an evolutionary stage might contain a mixture of different age cohorts at any time. Hence, when the stages are characterised by other features than the age, it might not be straightforward to provide a DDE model.

Beside population dynamics, predator-prey approaches have been previously considered in several

other fields of research, such as ecoepidemiology [5, 32] or tumour modelling [8]. The classes of predator-prey models presented in this paper can possibly be applied to these fields as they allow for more detailed modelling.
